Tunneling without tunneling: wavefunction reduction in a mesoscopic qubit

James A. Nesteroff and Dmitri V. Averin

(Dated: September 24, 2009)

The transformation cycle and associated inequality are suggested for the basic demonstration of the wavefunction reduction in a mesoscopic qubit in measurements with quantum-limited detectors. Violation of the inequality would show directly that the qubit state changes in a way dictated by the probabilistic nature of the wavefunction and inconsistent with the dynamics of the Schrödinger equation: the qubit tunnels through an infinitely large barrier. Estimates show that the transformation cycle is within the reach of current experiments with superconducting qubits.

PACS numbers: 03.65.Ta, 03.65.Ud, 85.25.Dq

Can a quantum particle tunnel through a barrier which has vanishing transparency? Immediate answer to this question is "no" as follows from the elementary properties of the Schrödinger equation. More careful consideration should of course remind that evolution according to the Schrödinger equation is not the only way for a state of a quantum particle to change in time. Probabilistic nature of the wavefunction implies that it can also evolve due to the "wavefunction reduction": random process of realization of one specific outcome of a measurement. In this process, the wavefunction of the system changes coherently for any given outcome of the measurement – see, e.g, [1, 2, 3], if measured with the "morally best" [2, 3] or, in a more modern and descriptive language, quantum-limited detector. Such an evolution of the measured system can contradict the Schrödinger equation despite the fact that the dynamics of the measurement process as a whole is governed by this equation. It can be described formally as generic quantum operation within the approach based on positive operator-valued measures (POVM) [4]. All "counter-intuitive" quantum-mechanical phenomena arise from the wavefunction reduction. The best known example is given by the EPR correlations which violate the principle of "no action at-a-distance" as quantified by the Bell's inequalities. They appear for specific random outcomes of the local spin measurements. On average, there is no action-at-a-distance, since the correlations do not violate the relativistic causality. In mesoscopic solid-state qubits, proposed and/or observed manifestations of the wavefunction reduction include violations of the temporal Bell inequalities [5, 6, 7, 8], measurements of the "weak values" of the operators [9, 10], stochastic reversal of the wavefunction reduction [11]. The purpose of this work is to suggest a sequence of quantum transformations and the corresponding inequality which illustrates directly the contradiction between the wavefunction reduction and the Schrödinger dynamics by violating the very basic intuition that a particle can not tunnel through an infinitely large barrier. For mesoscopic structures with their small geometric dimensions, violation of this intuition would provide, arguably, more dramatic illustration of the wavefunction reduction than the non-locality of conventional Bell's inequalities.

The system we consider is a qubit with the two basis states $|j\rangle$, $j = 0, 1$, distinguished by the average values of some quantity x, for instance, electric charge or magnetic flux [12, 13, 14, 15] in the case of superconducting qubits. As the simplest example, x can be viewed as a position of an individual particle (electron in coupled quantum dots [16, 17], Cooper pair on a superconducting island [12, 13], FQHE quasiparticle in a system of two quantum antidots [18, 19], or ultracold atom in a BEC junction [20, 21]) which can be localized on the opposite sides of a tunnel barrier separating the states $|j\rangle$ and creating tunnel amplitude $\Delta > 0$ between them (Fig. 1). The coordinate x is measured by a detector which converts the information about x into the classical output q. The detector is characterized by the probabilities $w_j(q)$ of producing the output q, when the qubit is in the state $|j\rangle$. For instance, in the example of the quantum-point-contact (QPC) detector (see, e.g., [22] and references therein), the qubit controls the scattering characteristics of electrons in the contact, and therefore the current I flowing through it (Fig. 1). In this case, the output q is the total charge transferred through the contact during the time τ of the measurement.

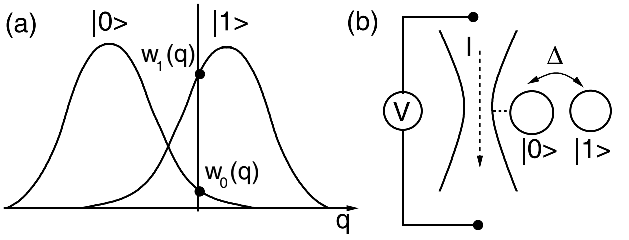

FIG. 1: Illustration of the qubit measurement process. (a) Typical probability distributions $w_j(q)$ of a detector output q for the qubit in the state $|j\rangle$, $j = 0, 1$. (b) Schematics of the particular measurement setup based on the QPC detector measuring mesoscopic "charge" qubit. In this case, the qubit states $|j\rangle$ differ by position of some elementary charge which controls the QPC transmission properties, and therefore, the current I in the contact driven by the applied voltage V.

The goal of the transformation cycle developed in this work is to demonstrate that the evolution of the wavefunction in the measurement process is "real" to the same extent as the dynamics of wavefunction governed by the Schrödinger equation, i.e., it describes evolution of the physical quantities and not only information about them. This is accomplished by combining the two types of evolution in one cycle arranged so that they completely compensate each other, leaving the initial qubit state unchanged. The first part of the cycle is the wavefunction reduction in a weak quantum-limited measurement which mimics the tunneling between the qubit states $|j\rangle$ through infinitely large barrier with $\Delta = 0$. The second part is the regular tunneling with $\Delta \neq 0$. The fact that no charge or flux is transferred through the tunneling barrier in the whole cycle means that the wavefunction reduction induces tunneling even without the corresponding tunneling amplitude.

The starting point of the cycle is a qubit with vanishing average bias $\epsilon = 0$ between the states $|j\rangle$. The Hamiltonian of such a qubit is

$$H = -(v\sigma_z + \Delta\sigma_x)/2 \,, \qquad (1)$$

where $\sigma_{x,z}$ are the Pauli matrices, and the bias v represents the low-frequency noise characteristic for mesoscopic solid-state qubits [23, 24, 25, 26]. Due to assumed weak, but unavoidable, relaxation, the qubit at low-temperature $T \ll \Delta$ is in the instantaneous ground state of (1) with the density matrix ρ_i in the σ_z basis

$$(I) \qquad \rho_i = \begin{pmatrix} c_0^2 & c_0c_1 \\ c_0c_1 & c_1^2 \end{pmatrix} , \qquad (2)$$

where the probability amplitudes c_j are $c_{0,1} = [(1 \pm v/\Omega)/2]^{1/2}$, and $\Omega = (v^2 + \Delta^2)^{1/2}$. For $\Delta \gg v_0$, where v_0 is the r.m.s. magnitude of noise v, the state (2) is the ideal version of initial state for our transformation cycle, the eigenstate $\sigma_x = 1$ of the σ_x operator with $c_{0,1} = 1/\sqrt{2}$. However, optimization of the cycle as a whole discussed below can require keeping the ratio Δ/v_0 finite, which reduces the noise-induced dephasing.

The cycle begins by rapidly (on the scale $\hbar/v_0$) raising the tunnel barrier so that the tunnel amplitude vanishes, $\Delta \to 0$, while the qubit wavefunction remains distributed between the states $|j\rangle$. The next step is a weak measurement of the σ_z operator performed on the qubit state (2) with a quantum-limited detector. Qualitatively, this means that the fluctuations underlying the probability distributions $w_j(q)$ of the detector output are themselves quantum, so that the evolution of the detector+qubit system leading to any given value q of the output is quantum coherent. An example of the quantum-limited detector is the QPC [22, 27] mentioned above (Fig. 1b), in which the distribution of the transferred charge q is created by the quantum-coherent scattering of electrons at the contact. The information about the qubit state gained by the measurement depends on the observed output q (Fig. 1a), and implies that the qubit wavefunction amplitudes c_j evolve into the q-dependent values $c_j(q)$ [27, 28]:

$$c_j(q) = \frac{c_j\sqrt{w_j(q)}}{\sqrt{w_0(q)|c_0|^2 + w_1(q)|c_1|^2}} . \qquad (3)$$

If the detector is not strictly quantum-limited, it induces partial dephasing of the qubit state even for a given specific detector output q. Physically, this dephasing is caused by the loss of information in the measurement process and can be described in general by the suppression factor $e^{-\eta}$ of the non-diagonal elements of the qubit density matrix ρ in the measurement basis. The qubit density matrix after weak σ_z measurement the is

$$(II) \qquad \rho_m = \begin{pmatrix} c_0^2(q) \,, & c_0(q)c_1(q)e^{-\eta+i\varphi(\tau)} \\ c_0(q)c_1(q)e^{-\eta-i\varphi(\tau)}, & c_1^2(q) \end{pmatrix} . \qquad (4)$$

The factor $e^{i\varphi(\tau)}$ here represents the noise-induced phase $\varphi(\tau) = \int_0^\tau dtv(t)/\hbar$ during the measurement time τ.

The aim of the next step of the cycle is to reverse the changes in the qubit amplitudes c_j due to redistribution through the tunnel barrier with vanishing transparency in the reduction process (3) by regular tunneling. This is done by creating a non-vanishing tunneling amplitude for some appropriate period of time, i.e., realizing a fraction of the regular coherent oscillations in which the charge or flux goes back and forth between the qubit basis states. In the situation with no disturbances (vanishing noise and quantum-limited detector), this can be done precisely, returning the qubit from the state

$$|\psi_m\rangle = [\sqrt{w_0(q)}|0\rangle + \sqrt{w_1(q)}|1\rangle]/\sqrt{w_0(q) + w_1(q)} \,.$$

obtained as a result of the measurement, to the initial state $|\psi_i\rangle = [|0\rangle + |1\rangle]/\sqrt{2}$ before the measurement. Writing the amplitudes of $|\psi_m\rangle$ as $\cos(\theta/2)$ and $\sin(\theta/2)$, one can see that the required transformation is the rotation about the y axis. For mesoscopic qubits, such a rotation corresponds to complex tunnel amplitude Δ' with $\arg \Delta' = \pi/2$, and the rotation angle is

$$\int dt \frac{|\Delta'(t)|}{\hbar} = \frac{\pi}{2} - \theta \,, \quad \theta = 2\tan^{-1}\left(\frac{w_1(q)}{w_0(q)}\right)^{1/2} . \qquad (5)$$

Typically, the qubit structure allows only for the real tunnel amplitude Δ – see the Hamiltonian (1), which realizes the x-axis rotations $R_x = \exp\{i\sigma_x \int \Delta(t)dt/2\hbar\}$ of the qubit. In this case, the y-axis rotation (5), $R_y = \exp\{-i\sigma_y \int |\Delta'(t)|dt/2\hbar\}$, can be simulated directly by the x-rotation of the same magnitude, if it is preceded and followed by the z-axis rotations: $R_y = R_z^{-1}R_xR_z$. The z-rotations $R_z^{\pm 1} = \exp\{\pm i\sigma_z\pi/4\}$ are created by the pulses of the qubit bias: $\int \epsilon(t)dt/\hbar = \pm\pi/2$. Such a three-step sequence is simplified by interchanging the order and magnitude of rotations: first the x-, then one z-rotation:

$$(III) \qquad \int dt \frac{\Delta(t)}{\hbar} = \frac{\pi}{2} \,, \quad \int dt \frac{\epsilon(t)}{\hbar} = \frac{\pi}{2} - \theta \,. \qquad (6)$$

Under the experimentally-realistic assumption that the measurement takes much longer time than control pulses, the noise-induced distortions of the qubit states is dominated by the phase accumulation in Eq. (4). The qubit density matrix after the pulses (6) then is

$$\rho = U\rho_m U^\dagger \, , \quad U = R_z(\pi/2-\theta)R_x(\pi/2)\, . \tag{7}$$

As the last step, one needs to check whether the qubit is brought back to the initial state $\sigma_x = 1$. This is done directly by strong measurement of σ_x, which gives, upon sufficiently large number of cycles, the error probability p of the qubit reaching the wrong state $\sigma_x = -1$:

$$(IV) \quad\quad p = \mathrm{Tr}[P\rho]\, , \quad P = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} . \tag{8}$$

If $p = 0$, the cycle $(I)-(IV)$ returns the qubit with certainty to the state $\sigma_x = 1$. This means that for any finite measurement strength, when the distributions $w_0(q)$ and $w_1(q)$ are not identical, the transfer of the qubit amplitudes due to the wavefunction reduction with $\Delta = 0$ is precisely compensated for by a fraction of a period of coherent qubit oscillations with $\Delta \neq 0$. Since the oscillations actually transfer the charge or flux between the two qubit basis states, the fact that the cycle is closed shows that the qubit evolution in the wavefunction reduction can not be interpreted only as the changes in our knowledge of the qubit state, but rather involve actual transfer of charge or flux without the tunneling amplitude.

In the presence of the finite noise and detector non-ideality, the error probability p is non-vanishing. Still, the probability $1-p$ of the closed cycle can be larger than the value explainable by the classical description of the measurement process, demonstrating that the actual qubit evolution in measurement is governed by the wavefunction reduction (3). The alternative classical description would be based on the assumption that the process of switching off the tunneling amplitude Δ does not leave the qubit in the state (2) but localizes it in one of the basis states on one or the other side of the tunnel barrier with some undetermined probability r, so that the qubit density matrix is $\rho^{(cl)} = r|0\rangle\langle 0| + (1-r)|1\rangle\langle 1|$. The qubit state is then "objectively" well-defined and coincides with one of the basis states. It is, however, unknown, and the measurement provides information about this unknown state changing the probability r:

$$r \to r(q) = rw_0(q)/(rw_0(q) + (1-r)w_1(q))\, .$$

Applying the same transformations as to the state (2) to $\rho^{(cl)}(q) = r(q)|0\rangle\langle 0| + (1-r(q))|1\rangle\langle 1|$, one finds the error probability $p^{(cl)}(q)$ given the measurement outcome q. Averaging over the probability $\sigma(q) = rw_0(q) + (1-r)w_2(q)$ of different q's, one obtains the total classical error probability

$$p^{(cl)} = \int dq \, \frac{w_0(q)w_1(q)}{w_0(q)+w_1(q)}\, . \tag{9}$$

Equation (9) shows that the probability $p^{(cl)}$ is independent of the assumed initial probability r, i.e. of noise v, and of the degree of detector non-ideality. The probability (9) characterizes the measurement strength, with $p^{(cl)} \to 0$ for strong projective measurements, when $w_0(q)w_1(q) = 0$, i.e. the measurement provides definite information about the qubit state. For weak measurements, the two distributions $w_{0,1}(q)$ nearly coincide and $p^{(cl)} \to 1/2$.

To see the incompatibility of the classical description with the actual qubit evolution, one needs to compare $p^{(cl)}$ (9) with the probability p found from Eqs. (7) and (8), after averaging over the detector output:

$$p = p^{(cl)}\left[1 - e^{-\eta} F\right] . \tag{10}$$

The factor F here describes effect of the noise v:

$$F \equiv \left\langle \frac{\Delta}{(v^2+\Delta^2)^{1/2}} \cos\!\int_0^\tau (v(t)dt/\hbar) \right\rangle . \tag{11}$$

Equation (10) shows that if the noise and the detector non-ideality are not very large: $F \to 1$ and $\eta \to 0$, the errors of the quantum cycle are suppressed regardless of the measurement strength characterized by $p^{(cl)}$, and it should be possible to observe that

$$p < p^{(cl)}. \tag{12}$$

Demonstration of this inequality would mean that a larger number of the transformation cycles are closed than can be explained classically, without invoking the transfer of the amplitude c_j across the infinite barrier. Note that Eq. (10) is obtained for essentially arbitrary noise model, and is therefore valid in the general case of the quantum noise that corresponds to entanglement of the qubit (1) with an arbitrary quantum system averaged out in Eq. (11).

To make the limitations on the noise more quantitative, we adopt the usual model of the low-frequency noise (see, e.g., [24, 26]) as a classical Gaussian random variable static on the time scale of the cycle, which gives

$$F = \frac{1}{\sqrt{2\pi}v_0} \int dv e^{-\frac{v^2}{2v_0^2}} \, \frac{\Delta \cos(v\tau/\hbar)}{(v^2+\Delta^2)^{1/2}}\, . \tag{13}$$

Equation (13) can be evaluated analytically in several limits. For $\Delta \gg v_0$, the noise effect on the initial state disappears, and Eq. (13) reduces for arbitrary $v_0\tau/\hbar$ to pure dephasing

$$F = e^{-v_0^2\tau^2/2\hbar^2}. \tag{14}$$

In the opposite limit of negligible dephasing, $v_0\tau/\hbar \ll 1$, or if dephasing is eliminated by a spin echo technique,

$$F = \sqrt{2a/\pi}\, e^a K_0(a)\, , \quad a \equiv \Delta^2/(4v_0^2)\, , \tag{15}$$

where K_0 is the modified Bessel function. This equation describes the transition from $F \simeq 1$ for $\Delta \gg v_0$, to $F \simeq$

$(\Delta/v_0)\ \ln(v_0/\Delta)$ for $\Delta \ll v_0$. For $\Delta \ll v_0$ and $\tau \neq 0$, one can neglect the exponential factor in (13) to get:

$$F = (2/\pi)^{1/2}(\Delta/v_0)K_0(\Delta\tau/\hbar)\,. \qquad (16)$$

The strength of the qubit coupling both to the detector and the noise depends typically on the same qubit parameters. This means that optimization for maximum F should be done for fixed values of the $v_0\tau$ product which represents a more fundamental quality of the qubit-detector system. Figure 2 shows F as a function of the Δ/v_0 ratio for several values of $v_0\tau/\hbar$ calculated numerically from Eq. (13). In the large-Δ limit, the curves saturate at F given by Eq. (14), which is exponentially small for strong noise. For $v_0\tau/\hbar \geq 2$, the Δ-dependence of F is non-monotonic, with the maximum at small Δ/v_0 representing suppression of dephasing by small Δ. Although the reduction of Δ increases the noise effect on the initial state, it effectively suppresses dephasing: the instances of stronger noise which would result in a stronger dephasing become irrelevant, since the qubit state is already localized for them in one of the states $|j\rangle$ and does not contribute to the wavefunction reduction. On the other hand, the probability of obtaining realizations with small noise scales as Δ/v_0, and F is also suppressed for $\Delta \to 0$. This gives the peak of F at small Δ/v_0 seen in Fig. 2 and for $v_0\tau/\hbar \gg 1$, described analytically by Eq. (16). This peak may be useful in experimental realization of the cycle discussed in this work.

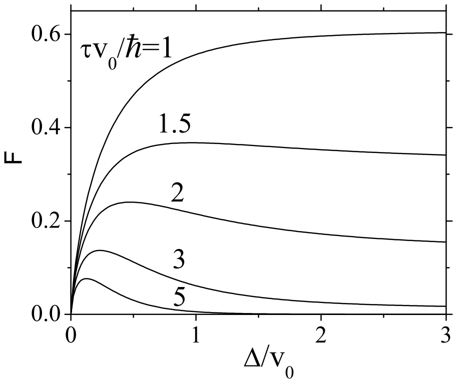

FIG. 2: The noise suppression factor (13) as a function of the Δ/v_0 ratio for several values of the noise strength or quality parameter $v_0\tau/\hbar$ of the qubit-detector system. For the discussion, see main text.

In general, realization of this cycle and observation of the inequality (12) is not very far from the possibilities of the current experiments with superconducting qubits. Indeed, Figure 2 shows that a noticeable difference between the classical and quantum error probabilities can be obtained even for the cycle times τ on the order of ~ 3 dephasing times (14) $\hbar/v_0$. Experimental dephasing times for the qubit states that differ by the average flux or charge values are about 5 ns – see, e.g., [15, 29], giving roughly 15 ns interval for performing three operations of the cycle when the qubit is subject to dephasing: measurement and two compensating pulses (6). Simple qubit control pulses are regularly performed on the few-nanosecond time scale, and can be fit into this interval. The new requirement presented by the cycle described above is the need to perform a variant of the feed-back control, when the applied pulses depend on the result of the previous qubit measurement. Necessary rapid non-destructive read-out could be developed, e.g., using the superconductor qubit control circuits [28].

In summary, we have proposed a transformation cycle aimed at the very basic demonstration of the two main features of the wavefunction reduction in quantum measurements using mesoscopic solid-state qubits. The wavefunction can evolve in a way that explicitly contradicts the dynamics of the Schödinger equation: a particle can be transferred through an infinitely large barrier. On the other hand, to the same extent as the Schödinger equation, the reduction affects not only the probability distributions of a dynamic variable (i.e., electric charge or magnetic flux), but the variable itself. Although the particle transfer through the infinite barrier in this process is not identical to the regular Schödinger-equation tunneling, e.g., there is no a corresponding current operator, the cycle developed in this work demonstrates that such a transfer can still take place and should be observable in current experiments with superconducting qubits.
